Primary Examiner—Ronald Stright
Attorney, Agent, or Firm—Gerald W. Spinks[57] **ABSTRACT**

A method and apparatus for injecting radiographic dye during angiography. A deformable holding chamber is interposed between a contrast dye bottle and a syringe manifold. A one-way valve and an integral disconnect/flow-stop are connected between the bottle and the holding chamber. A vent is provided in the holding chamber, which can include a second one-way valve. Squeezing and releasing the deformable chamber fills the chamber from the bottle. The holding chamber contains a floating baffle which acts as a shut off valve by plugging the chamber outlet if the chamber becomes empty. The syringe is used to withdraw dye from the holding chamber. If dye remains in the bottle after performance of the procedure, the disconnect/flow-stop fitting can be disconnected, and the dye can be saved.

METHOD AND APPARATUS FOR UNINTERRUPTED DELIVERY OF RADIOGRAPHIC DYE

CROSS REFERENCE TO RELATED APPLICATIONS

This is a continuation patent application of U.S. patent application Ser. No. 08/661,374, filed on Jun. 11, 1996, now U.S. Pat. No. 5,779,666 and entitled "Method and Apparatus for Uninterrupted Delivery of Radiographic Dye", which was a continuation of U.S. Ser. No. 08/336,252, filed Nov. 7, 1994, now U.S. Pat. No. 5,533,978, both of which are incorporated by reference herein.

STATEMENT REGARDING FEDERALLY SPONSORED RESEARCH OR DEVELOPMENT

Not Applicable

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention is in the field of angiography using a liquid contrast dye.

2. Background Information

A procedure commonly performed is the catheterization of the cardiovascular system of a patient, requiring the performance of angiography to assist the physician in visualizing the catheter and other instruments within the blood vessels. Typical of procedures for which catheterization is performed are atherectomy and angioplasty procedures. During angiography, a radiopaque contrast dye or other medium is usually injected into the vascular system to render the lumen of the vessel visible via radiographic equipment.

The contrast dye is typically provided in containers such as bottles with puncturable receptacles. The receptacle is punctured with a spike, which can be vented, and the spike is typically connected to the proximal end of a flexible tube. The bottle is hung from a stand to provide a hydrostatic head, and the distal end of the flexible tube can be connected to a manifold or other valving device. The manifold is also connected to a syringe and to the proximal end of a guide catheter, the distal end of which is inserted into the vascular system of the patient.

During the catheterization procedure, when the physician wishes to inject dye into the blood vessel, the plunger of the syringe is first withdrawn, with the manifold or other valves aligned as required to allow flow of dye from the contrast bottle, through the tubing and the manifold, to the syringe. The manifold valves are then realigned as necessary, to allow flow from the syringe to the guide catheter, and the plunger is pushed into the syringe to dispense contrast dye into the patient's vascular system, through the manifold and the guide catheter. After the syringe is emptied, if another dye injection is required, the physician again draws dye from the bottle into the syringe and dispenses the dye into the guide catheter.

Two problems can result from this conventional method of dye injection. First, the method is unnecessarily expensive, because it wastes large amounts of very expensive contrast dye. Each cardiovascular catheterization procedure typically only requires about 70 or 80 milliliters of contrast dye. After performance of the typical procedure, some of the contrast dye usually will be left in the bottle. This remaining dye can not be used in a subsequent procedure on another patient, because of the risk of contamination.

2

In other words, contaminated fluids from the first patient might conceivably flow back through the syringe to the contrast bottle, subsequently contaminating the second patient. To guard against this possibility, the contrast dye remaining in a bottle typically is discarded. If large bottles are used, a large amount of dye can be wasted. Considering that the contrast material costs approximately one dollar per milliliter, this practice results in substantial unnecessary expense.

Secondly, when the physician repeatedly fills the syringe, if the contrast bottle approaches empty, air will eventually be drawn into the tubing and possibly into the syringe. This requires stopping the catheterization procedure while a new bottle of fluid is attached, and while the air is purged from the syringe and the tubing. If smaller bottles are used to limit waste, additional time in surgery can be required for repeatedly changing bottles and repriming the flowpath. Given the invasive nature of cardiac catheterization in particular, and given the fact that blood flow in the affected vessel is substantially reduced during the procedure, any delay in the procedure is very undesirable.

It is an object of the present invention, then, to provide a method and apparatus for injecting radiographic dye into a vascular system, which will allow the use of essentially all of the contrast material in a bottle before discarding the bottle, without fear of contamination. It is a further object of the present invention to provide a method and apparatus for injecting radiographic dye into a vascular system, which will allow the replacement of an empty contrast bottle with a replacement bottle, without stopping the procedure. Finally, it is an object of the present invention to provide a method and apparatus for injecting radiographic dye into a vascular system, which is easy and economical to implement.

BRIEF SUMMARY OF THE INVENTION

A preferred embodiment of the present invention, for illustrative purposes only, includes a method and apparatus for injecting radiographic dye during cardiovascular catheterization that interposes a deformable holding chamber between the contrast bottle and the syringe manifold. Flow control devices are installed to allow rapid filling of the holding chamber, replacement of an empty bottle with a full bottle without interrupting the procedure, and separation of the holding chamber from a partially emptied contrast bottle to permit use of the remainder of the contrast dye in a subsequent procedure. A tube is connected between the vented spike in the contrast bottle and the holding chamber, with two flow control devices installed at intermediate positions along the tube. A floating baffle of latex or some other impermeable membrane, stretched across a floating frame, is contained within the holding chamber. As the level of dye in the holding chamber reaches the bottom of the chamber, the impermeable membrane covers and plugs the chamber outlet to prevent air from entering the outlet line from the holding chamber.

The first flow control device in the tube between the vented spike and the holding chamber is a disconnect fitting with an integral automatic flow-stop. The fitting is a device available on the market, which has two halves joined by mating threads. Each half of the fitting is connected to the tubing so as to cause all flow through the tubing to flow through the fitting. Disconnection of the fitting, thereby disconnecting the tubing, is accomplished by separating the two halves of the fitting at the threads. The upstream half of the fitting, connected to the tubing leading from the contrast bottle, contains an integral automatic flow-stop. When the

5,911,708

3

two halves of the fitting are separated at the threads, the flow-stop automatically closes, preventing flow through the upper half of the fitting.

The second flow control device is a one way valve which is installed to allow flow only from the contrast bottle into the holding chamber. The one way valve can be one of a number of such devices available on the market. It should be suitable for preventing even low flow rates in the reverse direction. This device is installed in the tubing between the disconnect/flow-stop fitting and the holding chamber. Therefore, the one way valve prevents flow of fluid from the holding chamber back to the contrast bottle while the tubing is still connected, and it prevents flow of fluid out of the holding chamber to the atmosphere after the tubing is disconnected.

A third device which can optionally be installed on the tubing between the contrast bottle and the holding chamber is an air-in-line sensor, which can be one of several available on the market. It can, for instance, be ultrasonically operated, or based on infrared or photoelectric technology. This sensor can detect air or other gas in the tubing, such as an air bubble which might enter the tubing if the contrast bottle empties unnoticed by the physician. When air is sensed by this sensor, an alarm is sounded, and the contrast bottle can be replaced with a full bottle before air enters the tubing leading to the syringe manifold. This obviates the need to stop the procedure, since contrast medium will still be available in the holding chamber for any injections that are needed during bottle replacement. This can also facilitate the removal of air from the tubing after replacement of the contrast bottle, since as will be seen, repriming of the holding chamber will automatically remove the entrapped air from the tubing upstream of the holding chamber. As an alternative, the air sensor can be installed on the outside of the holding chamber at a selected level to warn that the level of dye in the chamber is falling. The selected level would be below the normal full level but above the empty level to insure that several injections are still available while the dye bottle is being exchanged.

The deformable chamber is also fitted with a pierceable seal and a vent opening. The pierceable seal allows secondary injections or connections as desired. The vent opening is fitted with a second one way valve, which can be operated by a low pressure differential, like the first one way valve, or it can be a high pressure crack valve which opens only upon seeing a relatively high pressure differential across the valve. The second one way valve is oriented to allow flow only out of the holding chamber to the atmosphere. If desired, a manual stop valve can be installed in the vent line between the second one way valve and the holding chamber. The manual stop valve is required only if the one way valve in the vent is a typical one way valve having a relatively low cracking pressure. If the second one way valve is a high pressure crack valve, the manual valve is not needed.

In order to use the apparatus of the present invention, the vented spike is inserted into the receptacle on the contrast bottle, and the bottle is hung on a stand. If installed, the manual stop valve on the holding chamber vent is opened. Then, the deformable holding chamber is squeezed and released one or more times, to expel air out the chamber vent and draw contrast dye into the chamber from the contrast bottle. This process is repeated until the holding chamber contains the desired amount of dye, preferably about 30 milliliters. Then, the manual valve on the holding chamber vent is closed, if one is installed. Partial filling of the holding chamber leaves an air space in the chamber, which acts as a contamination barrier when combined with the presence of the first one way valve in the inlet tube.

4

The presence of the vent on the holding chamber allows the holding chamber to be filled much more rapidly than if the venting of the apparatus were to be done entirely through the dye bottle, as was seen in the prior art device. Moreover, the presence of the second one way valve in the vent line promotes the rapid filling of the holding chamber. Squeezing the holding chamber forces air out the vent through the second one way valve. When the holding chamber is released and allowed to expand to its original size, the second one way valve prevents air from flowing back into the holding chamber through the vent. This ensures the formation of a vacuum in the holding chamber to draw dye into the chamber from the dye bottle, via the first one way valve.

When the physician wishes to inject dye into the patient, the manifold valves are aligned to allow flow from the holding chamber into the syringe. Then, the syringe plunger is withdrawn to draw dye from the holding chamber into the syringe. As dye is drawn into the syringe from the holding chamber, replacement dye is drawn into the holding chamber from the contrast bottle. The manifold valves are then aligned to allow flow from the syringe into the guide catheter, and the plunger is pushed into the syringe to dispense dye into the patient.

If the procedure is completed without using all of the dye in the contrast bottle, the bottle can be removed and saved for another procedure by disconnecting the disconnect/flow-stop fitting. The equipment downstream from the fitting, including the lower half of the fitting, can be discarded. The equipment upstream of the fitting is safe to save, since the interposition of the holding chamber and the one way valve between the disconnect/flow-stop fitting and the patient insures that no contamination can reach the fitting.

If the contrast material in the bottle is exhausted before the procedure is complete, the bottle can be removed by removing the spike from the bottle and inserting it into a new bottle. After a replacement bottle is connected, the holding chamber and the tubing from the contrast bottle can be reprimed by squeezing and releasing the holding chamber as before, if required.

The novel features of this invention, as well as the invention itself, will be best understood from the attached drawings, taken along with the following description, in which similar reference characters refer to similar parts, and in which:

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWINGS

FIG. 1 is a schematic diagram of a typical dye injection apparatus as is known in the art; and

FIG. 2 is a schematic diagram of the dye injection apparatus of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

As seen in FIG. 1, a typical dye injection apparatus as is known in the art includes three basic components. Specifically they are a contrast dye bottle 12, a dye manifold 16, and a syringe 50. The contrast bottle 12 is connected to the manifold 16 by a vented spike 24 and a length of tubing 20. The manifold 16 is also connected to a branch of a guide catheter (not shown) by a second length of tubing 22.

The vented spike 24 is inserted into the bottle 12 via a receptacle in the mouth of the bottle 12. As fluid is drawn from the bottle 12, air is drawn into the bottle 12 through the

5,911,708

5

branch of the spike **24**, as shown by the arrow. The fluid conduit of the spike **24** is connected to the proximal end of the flexible tubing **20**. The distal end of the tubing **20** is connected to an inlet valve **42** on the manifold **16**. Typically, a manifold **16** will also have other valves **44**, **46**, as well as an outlet valve **48**. A proximal end of the second tubing **22** is connected to the outlet valve **48**. Finally, the syringe **50** is connected to the manifold **16**. The manifold **16** could have various types of valves, including manual valves or check valves, to control the flow of the contrast dye. Indeed, the manifold **16** could be replaced by a multi-ported ball valve. However, the functioning of the apparatus can be most easily illustrated by discussion of a manifold **16** having manual valves as shown.

Once connected as shown, the known apparatus must be primed by drawing dye into the syringe and dispensing it into the guide catheter, including the purging of all air bubbles from the manifold **16** and the tubing **20**. This is a time consuming operation. When it is desired to inject contrast dye into the patient, the physician withdraws the plunger of the syringe **50**, with inlet valve **42** open and outlet valve **48** closed. When the syringe **50** is filled with dye, inlet valve **42** is shut and outlet valve **48** is opened. Then, the plunger is inserted back into the syringe **50**, dispensing the dye through the manifold **16**, and through the tubing **22**, to the guide catheter. Each injection will typically dispense approximately 7 ml. of dye. Repeated injections are repeated as required. After the angiography procedure has been completed, approximately half of the dye in bottle **12** will remain. The entire apparatus, including the remaining dye, must be discarded, since there is no assurance that contaminated fluid has not migrated back up through the apparatus into the bottle **12**.

FIG. 2 shows a preferred embodiment of the apparatus of the present invention **10**. The contrast bottle **12** is ultimately connected, as before, to the manifold **16** and the syringe **50**. In this case, however, apparatus is interposed between the bottle **12** and the manifold **16** to ensure that contamination does not migrate back to the bottle **12**, and to facilitate disconnection of the bottle **12** from the other apparatus, to allow saving the remaining dye in the bottle **12**, or to allow replacement of an empty bottle with a full bottle.

The intervening apparatus consists of a deformable holding chamber **14**, which is connected to the bottle **12** by several additional components in a flow path **18**. Connected to the fluid conduit of spike **24** is the proximal end of a length of tubing **26**, forming a portion of the flow path **18**. Continuing along flow path **18**, the distal end of the tubing **26** is connected to the proximal end of a disconnect/flow-stop fitting **28**. The disconnect/flow-stop fitting **28** consists essentially of two portions, a flow-stop portion **32** and a threaded disconnect portion **30**. The fitting **28** can be one of a number of such fittings available on the market. When the threaded disconnect portion **30** is disconnected, thereby breaking the flow path **18**, the integral flow-stop portion **32** automatically stops flow through the flow path **18** from the bottle **12**.

The distal end of the fitting **28** is connected to the proximal end of a second length of tubing **34**, the distal end of which is connected to the proximal end of a one-way valve **36**. The one-way valve **36** allows flow only from the bottle **12** toward the holding chamber **14**, as shown by the arrow. The one-way valve **36** can be one of a number of such valves available on the market. The distal end of the one-way valve **36** is connected to the proximal end of a third length of tubing **38**, completing flow path **18**. Indeed, the three lengths of tubing **26**, **34**, **38** can be seen to constitute

6

essentially a single tubing with the disconnect fitting **28** and the one-way valve **36** interposed therebetween.

The tubing **38** can have attached thereon an air-in-line sensor, or bubble detector **60**. The bubble detector **60** can be one of several such devices available on the market, which can operate on ultrasonic, photoelectric, or infrared technology. When a gas bubble is detected in the tubing **38**, the sensor **60** will give an alarm signal to alert personnel to the need to replace the bottle **12** with a full bottle.

Alternatively, an air sensor **60'** can be mounted on the holding chamber **14** to determine when the dye level has fallen below a selected level. Normally, the sensor **60'** will be mounted at a level selected to be below the normal fill level in the chamber **14**, but above the bottom of the chamber **14**. Ideally, the level at which the sensor **60'** is mounted will leave at least enough dye to supply several injections of dye after the air alarm is given. As dye is withdrawn from the holding chamber **14**, a partial vacuum in the holding chamber **14** will draw additional dye from the bottle **12**, causing the dye level in the holding chamber **14** to remain relatively constant. This means that the floating baffle **52** will normally remain above the level at which the sensor **60'** is mounted, and the sensor **60'** will not detect the presence of air. If the bottle **12** empties, repeated injections of dye into the patient will cause the baffle **52** to drop below the level of the sensor **60'**, and the air alarm will be energized.

An injection fitting **40** and a vent **54** are also mounted on the deformable chamber **14**. The injection fitting **40** is fitted with a pierceable seal, allowing the injection of secondary fluids with a hypodermic needle, or allowing the connection of a secondary set of tubing as desired. The vent **54** is fitted with a stop valve **56** and a second one-way valve **58**. The second one-way valve **58** is installed so as to allow flow only out of the holding chamber **14** to the atmosphere, as shown by the arrow. If the one-way valve **58** is a high pressure crack valve, the manual valve **56** is not needed.

The holding chamber **14** itself is a deformable chamber which is constructed so as to return to its original shape after being squeezed and released, with the resiliency being sufficient to draw dye out of the bottle **12** during return of the chamber **14** to its original shape. It should have visibility through at least a portion of its side wall, to allow personnel to see the level of dye therein. It should also have graduated markings on its side, and its capacity should be at least 30 ml. The baffle **52**, such as a floating baffle, can be provided within the chamber **14**, to prevent the entrainment of air in the dye by direct impingement of the stream of dye on the reservoir of dye in the bottom of the chamber **14**. The baffle **52** consists of a floating frame and an impermeable membrane such as a latex membrane. As dye falls on top of the membrane, it flows around the outside of the frame, which loosely fits the inner diameter of the holding chamber **14**. As the level of dye in the holding chamber **14** drops, the floating baffle **52** drops on top of the outlet of the chamber **14** and the impermeable membrane stops all flow out of the outlet.

With the apparatus **10** connected as shown in FIG. 2, and with contrast dye in the bottle **12**, the vent valve **56** is opened. Then, the holding chamber **14** is squeezed and released several times to expel air from the holding chamber **14** through the vent **54**, and to draw dye into the chamber **14** through the flow path **18**. Filling of the chamber **14** is rapid because of the pumping effect of the deformable chamber **14**, and because of the large capacity of the vent **54**, as compared to venting only through the relatively small vented spike **24** as in the prior art. When the desired level of

5,911,708

7

dye, typically about 30 ml., is in the holding chamber 14, the vent valve 56 is closed. This will leave an air gap in the top of the holding chamber 14.

When an injection is required, the plunger of the syringe 50 is withdrawn, with inlet valve 42 open and outlet valve 48 closed, and the dye is then dispensed by reinserting the plunger into the syringe 50, with the inlet valve 42 closed, and with the outlet valve 48 open. As mentioned before, these valves 42,48 could be check valves or a single multi-port ball valve. As dye is withdrawn from the chamber 14 by the syringe 50, it is replaced by dye flowing from the bottle 12 to the chamber 14, because of the partial vacuum created in the chamber 14. Repeated injections can be accomplished by repeating the procedure as required.

If dye material is remaining in the contrast bottle 12 after the angiography is completed, the disconnect fitting 30 can be threadedly disconnected from the integral flow-stop 32, whereupon the integral flow-stop 32 will stop flow from the bottle 12. Alternatively, the spike connector 24 can be removed from the bottle 12, and a new spike connector 24 can be reinserted in the bottle 12 when the bottle 12 is used again. Since the patient has at all times been separated from the bottle 12 by an air gap in the holding chamber 14 and by the one-way valve 36, the dye remaining in the bottle 12 is sterile and can be used in a subsequent procedure.

If the bottle 12 becomes empty during the procedure, the bubble detector 60, 60' if installed, will warn attendants to replace the bottle 12 with a full bottle. Since there will be approximately 30 ml. of dye available in the chamber 14, there is ample time for the bottle to be replaced. After bottle replacement, the deformable chamber 14 can be repeatedly squeezed and released, with vent valve 56 open if present, to quickly return the level of dye in the chamber 14 to the desired level. This eliminates the need to purge air from the tubing 20, and repriming is accelerated by the deformability of the chamber 14. If the bubble detector 60, 60' is not installed, the holding chamber 14 affords an additional visible indication of the amount of dye remaining.

Further, flow path 18 includes a number of restricted passageways in the flow-stop 32 and in the one-way valve 36 which offer some resistance to liquid flow. Therefore, if the bottle 12 empties, followed by the emptying of the flow path 18, drawing of dye into the syringe 50 will become increasingly easy, because of the fact that air rather than liquid dye is being drawn through the flow path 18. This will offer the physician an additional indication that the bottle 12 is empty, while dye is still available in the chamber 14. If the dye level in the holding chamber 14 falls sufficiently, the baffle 52 will settle onto the outlet of the chamber 14 and act as a shut off valve to prevent air from entering the outlet line.

While the particular invention as herein shown and disclosed in detail is fully capable of obtaining the objects and providing the advantages hereinbefore stated, it is to be understood that this disclosure is merely illustrative of the presently preferred embodiments of the invention and that

8

no limitations are intended other than as described in the appended claims.

I claim:

1. A fluid delivery system, comprising:
 - a fluid reservoir, said fluid reservoir having an outlet;
 - a deformable fluid holding chamber, said holding chamber having an inlet and an outlet;
 - a fluid shut off valve in said holding chamber for shutting off said outlet of said holding chamber when said holding chamber becomes empty;
 - a tubular conduit connecting said outlet of said reservoir in fluid flow communication with said inlet of said holding chamber;
 - a one way valve connected in said tubular conduit, said one way valve permitting flow only from said reservoir to said holding chamber; and
 - an air vent in fluid flow communication with said holding chamber.
2. A fluid delivery system as recited in claim 1, further comprising a vent valve connected in fluid flow communication with said air vent, said vent valve being capable of selectively permitting air flow from said holding chamber to the atmosphere.
3. A fluid delivery system as recited in claim 2, wherein said vent valve is a manual valve.
4. A method of injecting radiographic dye into a vascular system of a patient, said method comprising:
 - providing a radiographic dye reservoir, a deformable dye holding chamber connected to said dye reservoir via a one way valve, a shut off valve within said holding chamber, and a vent on said holding chamber;
 - squeezing said holding chamber to expel air from said holding chamber to the atmosphere through said vent;
 - stopping flow through said vent;
 - releasing said holding chamber to allow said holding chamber to expand and draw dye from said reservoir into said holding chamber through said one way valve;
 - withdrawing dye from said holding chamber with a syringe; and
 - dispensing dye from said syringe into a vascular system of a patient.
5. A method of injecting radiographic dye as recited in claim 4, further comprising:
 - providing a vent valve in fluid flow communication with said vent; and
 - stopping said flow through said vent with said vent valve.
6. A method of injecting radiographic dye as recited in claim 4, further comprising:
 - providing a manual vent valve in fluid flow communication with said vent; and
 - stopping said flow through said vent by closing said manual vent valve.
